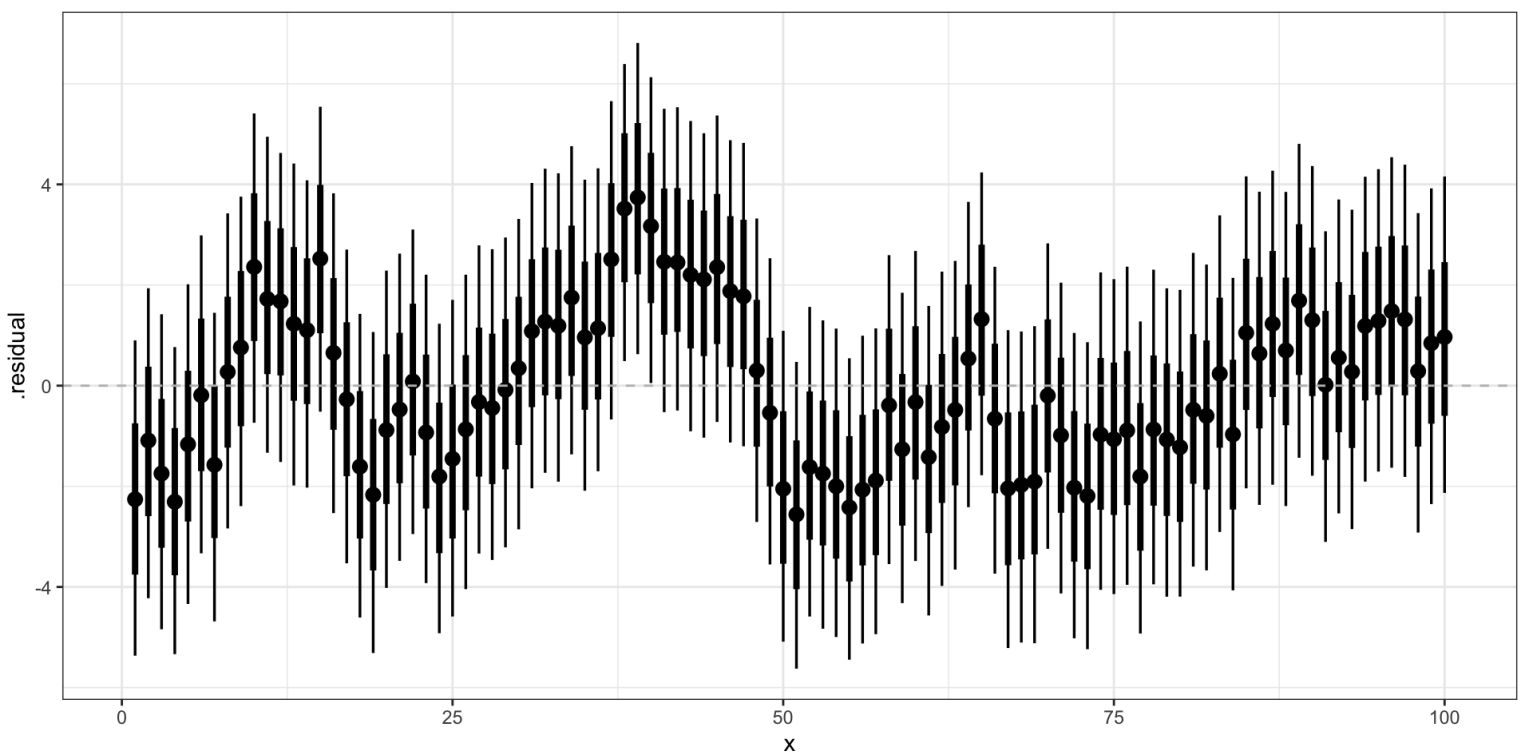
  ggplot(aes(x=x, y=.residual, group=x)) +
    ggdist::stat_pointinterval() +
    geom_hline(yintercept = 0, color='grey', linetype=2)
```



Model Evaluation

Model assessment

If we remember back to our first regression class, one common option is R^2 which gives us the variability in y explained by our model.

Quick review:

$$\underbrace{\sum_{i=1}^{n}(y_i - y)^2}_{\text{Total}} = \underbrace{\sum_{i=1}^{n}(\hat{y_i} - y)^2}_{\text{Model}} + \underbrace{\sum_{i=1}^{n}(y_i - \hat{y_i})^2}_{\text{Error}}$$

$$R^2 = \frac{SS_{model}}{SS_{total}} = \frac{\sum_{i=1}^{n}(\hat{Y_i} - Y)^2}{\sum_{i=1}^{n}(Y_i - Y)^2} = \frac{Var(\hat{\boldsymbol{Y}})}{Var(\boldsymbol{Y})} = Cor(\boldsymbol{Y}, \hat{\boldsymbol{Y}})^2$$

Some data prep

```
( b_post_full = b |>
    tidybayes::spread_draws(b_Intercept, b_x, sigma) |>
    tidyr::expand_grid(d) |>
    mutate(
      y_hat = b_Intercept + b_x * x,
      resid = y - y_hat
    )
)
```

```
# A tibble: 400,000 × 10

Bayesian R^2

When we compute any statistic for our model we want to do so at each iteration so that we can obtain the posterior distribution of that particular statistic (e.g. the posterior distribution of R^2 in this case).

```
( b_R2 = b_post_full |>
    group_by(.iteration) |>
    summarize(
      R2_classic = var(y_hat) / var(y),
      R2_bayes   = var(y_hat) /
                   (var(y_hat) + var(resid))
    )
)
```

```

What if we collapsed first?

Here we calculate the posterior mean of $\hat{y}$ and use that to estimate R^2,

```
b_post_full |>
  group_by(x) |>
  summarize(
    y_hat = mean(y_hat),
    y = mean(y),
    resid = mean(y - y_hat),
    .groups = "drop"
  ) |>
  summarize(
    R2_classic = var(y_hat) / var(y),
    R2_bayes   = var(y_hat) / (var(y_hat) + var(resid))
  )
```

```
# A tibble: 1 × 2
  R2_classic R2_bayes
       <dbl>    <dbl>
1      0.626    0.626
```

Some problems with R^2

Some new issues,

- R^2 doesn't really make sense in the Bayesian context
  - multiple possible definitions with different properties
  - fundamental equality doesn't hold anymore
  - Possible to have $R^2 > 1$

Some old issues,

- R^2 always increases (or stays the same) when adding a predictor
- R^2 is highly susceptible to over fitting
- R^2 is sensitive to outliers
- R^2 depends heavily on values of y (can differ for two equivalent models)

Some Other Metrics

Root Mean Square Error

The traditional definition of rmse is as follows

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{y}_i\right)^2}$$

In the bayesian context, we have posterior samples from each parameter / prediction of interest so we can express this as

$$\frac{1}{m}\sum_{s=1}^{m}\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{y}_{i,s}\right)^2}$$

where m is the number of iterations and $\hat{Y}_i^s$ is the prediction for Y_i at iteration s.

Continuous Rank Probability Score

Another approach is the continuous rank probability score which comes from the probabilistic forecasting literature, it compares the full posterior predictive distribution to the observation / truth.

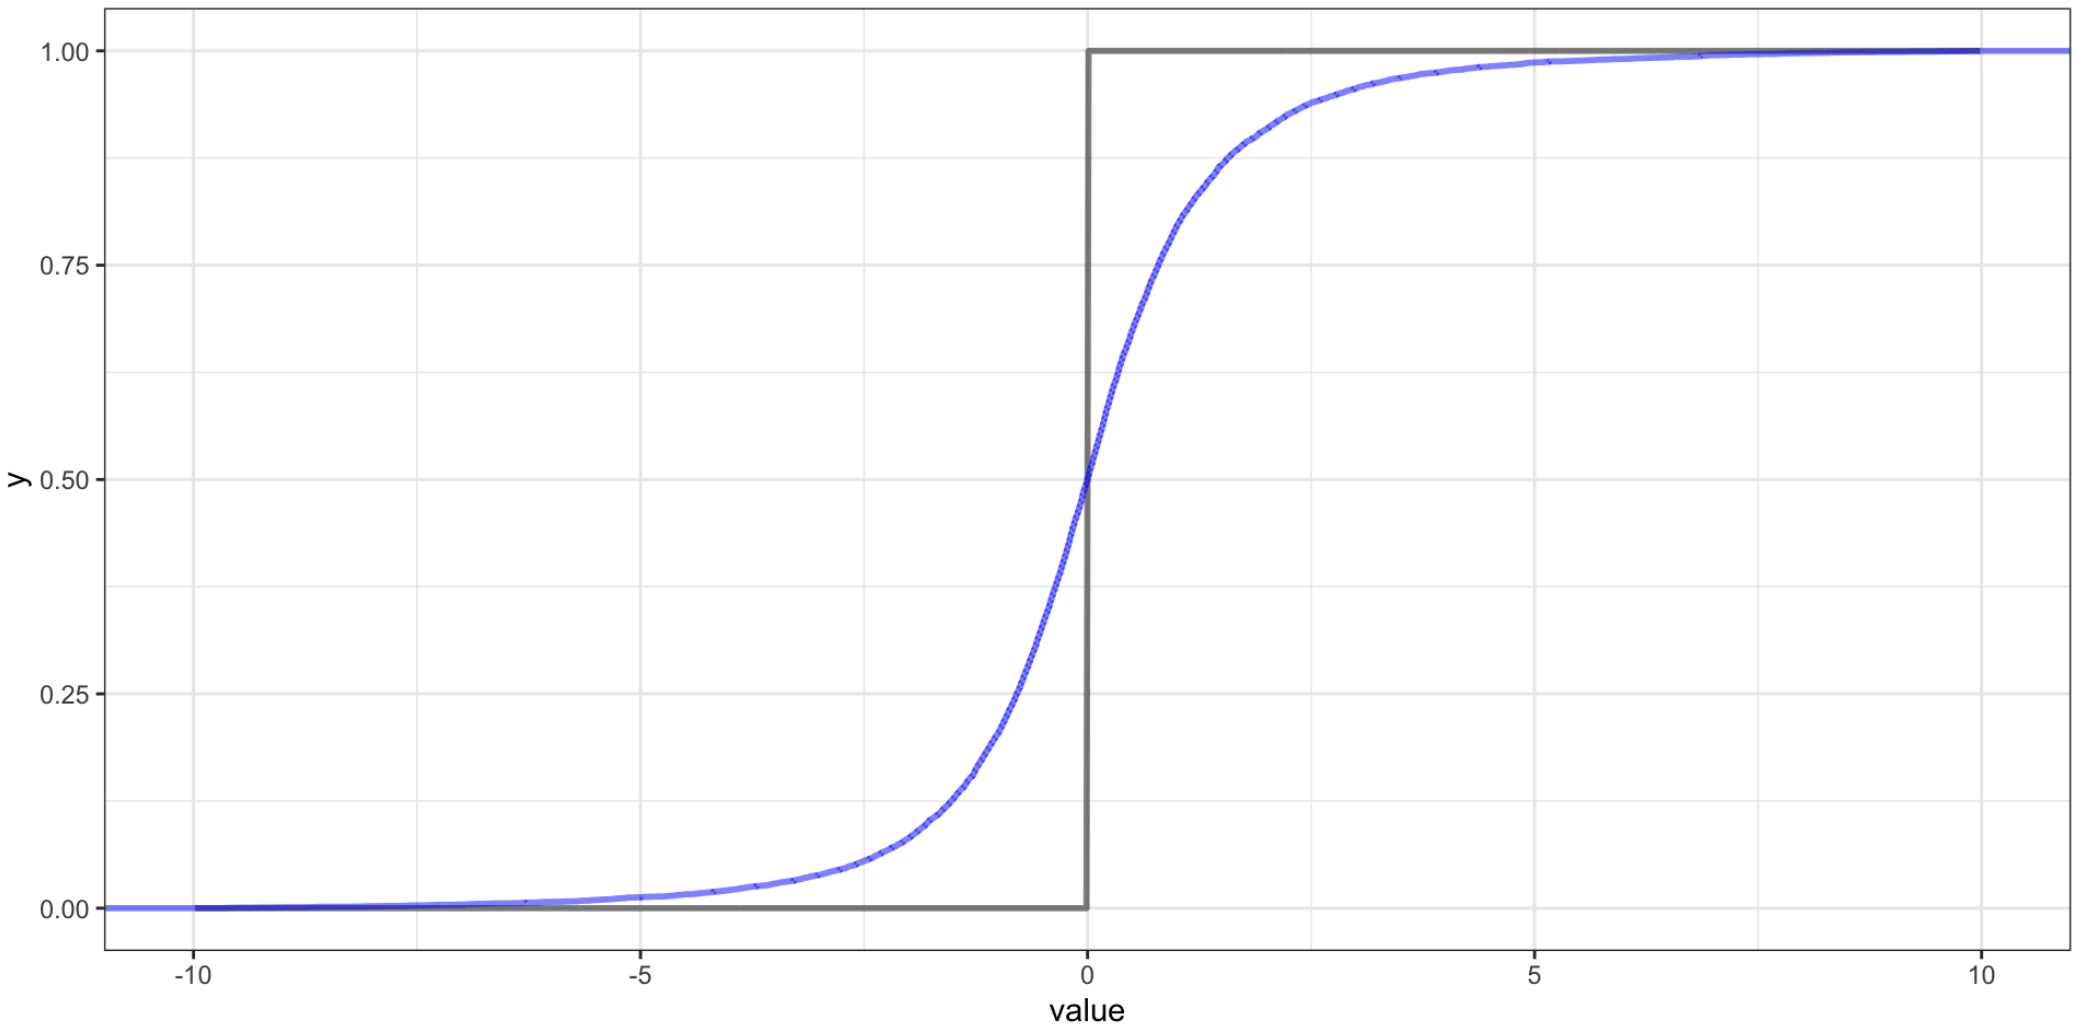
$$\text{CRPS} = \int_{-\infty}^{\infty} \left(F_{\hat{y}}(z) - 1_{z \geq y}\right)^2 dz$$

where $F_{\hat{y}}$ is the CDF of $\hat{y}$ (the posterior predictive distribution for y) and $1_{z \geq Y}$ is an indicator function which equals 1 when $z \geq y$, the true/observed value of y.

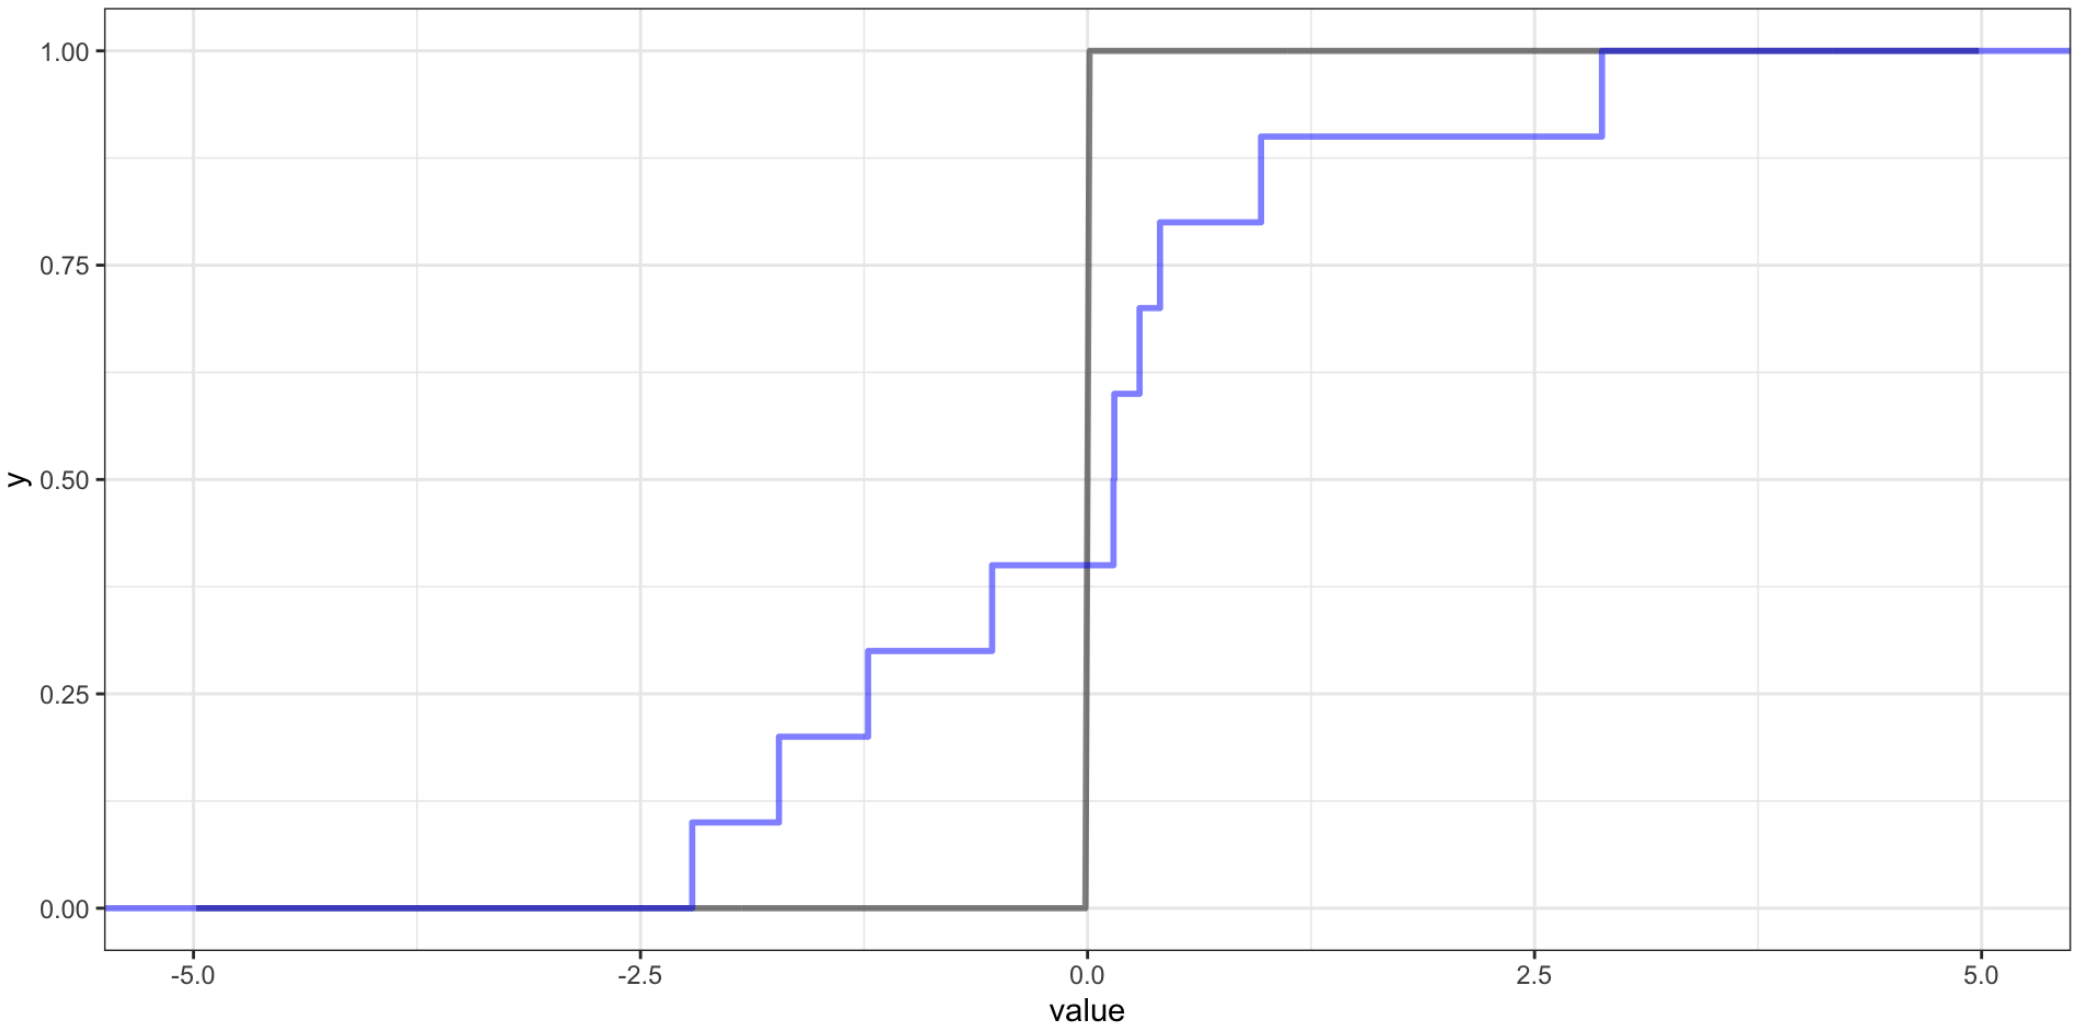
Since this calculates a score for a single probabilistic prediction we can naturally extend it to multiple predictions by calculating an average CRPS

$$\frac{1}{n} \sum_{i=1}^{n} \int_{-\infty}^{\infty} \left(F_{\hat{y}_i}(z) - 1_{z \geq y_i}\right)^2 dz$$

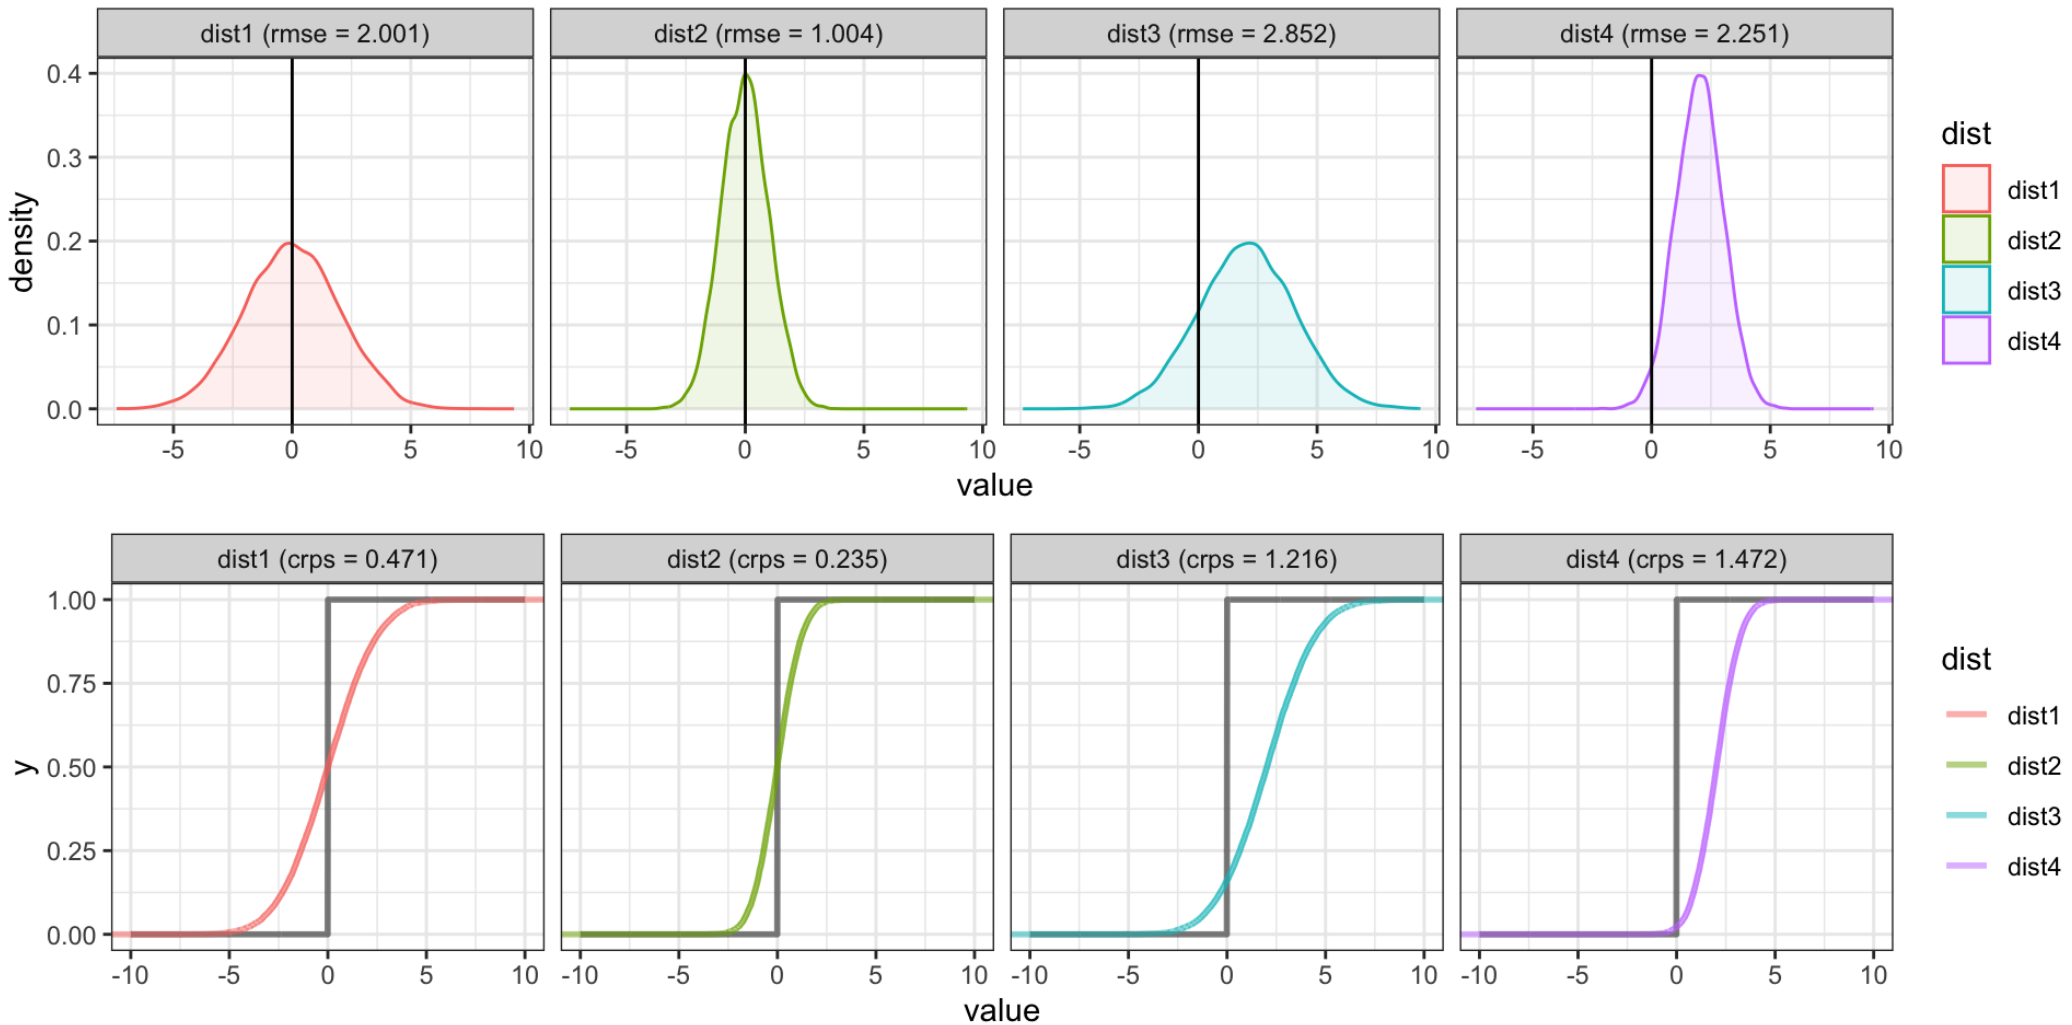
CDF vs Indicator



Empirical CDF vs Indicator



Accuracy vs. Precision



Empirical Coverage

One final method, which assesses model calibration is to examine how well credible intervals, derived from the posterior predictive distributions of the ys, capture the true/observed values.

Back to our example

RMSE
